Abstract

We present a new approach to construction of protocols which are proof against communication errors. The construction is based on a generalization of the well known Ulam's game. We show equivalence between winning strategies in this game and robust protocols for multi-party computation. We do not give any complete theory. We want rather to describe a new fresh idea. We use a tree code defined by Schulman. The tree code is the most important part of the interactive version of Shannon's Coding Theorem proved by Schulman. He uses probabilistic argument for the existence of a tree code without giving any effective construction. We show another proof yielding a randomized construction which in contrary to his proof almost surely gives a good code. Moreover our construction uses much smaller alphabet.

1 Introduction

We consider a generalization of the communication model introduced by Yao [9]. Processors $P_1, P_2, \dots, P_k$ compute a k -argument function $f: X_1 \times X_2 \times \dots \times X_k \rightarrow Y$. Initially processor P_i knows only the argument $x_i \in X_i$. In each communication step some of the processors send messages to some other processors. Each message consists of bits. The communication terminates when all the parties know the value $f(x_1, x_2, \dots, x_k)$. The *communication complexity* of the function f is the minimum number of exchanged bits which are required to solve the problem, measured on a "worst" input.

In this paper we add noise to the communication. We consider two kinds of noisy binary symmetric channels. In an *probabilistic channel* bits are incorrectly transmitted with a given probability $\varepsilon > 0$. In an *adversarial channel* the fraction of incorrectly transmitted bits is at most $\varepsilon > 0$. We assume that noise can cause bit inversion but bits are never lost and never any extra bit is added.

*Supported by the European Community Research Training Network GAMES and Polish KBN grant No. 4 T11C 042 25.

Our aim is to construct a protocol which is proof against noise, computes function f and exchanges $n = \Theta(n_0)$ bits, where n_0 denotes the communication complexity in the case when the processors are connected by noiseless channels and the constants implicit in the $\Theta(\cdot)$ notation depend only on ε . For an adversarial channel the protocol should always return a good result. For a probabilistic channel it should fail with probability bounded by $e^{-\Omega(n_0)}$. Rajagoplan and Schulman [4, 5] show that this is possible for a probabilistic channel. Moreover Schulman concludes in [5] about an adversarial channel in the case of two processors. But the proofs in those papers are not constructive.

We concentrate on protocols for an adversarial channel. It should be clear that the robustness against an adversarial channel is a stronger property than the robustness against a probabilistic channel. The following Lemma states this precisely.

Lemma 1 *If a protocol $\mathcal{P}$ exchanges n bits and is proof against any number of errors less than $\varepsilon_0 n$, then the protocol $\mathcal{P}$ fails with probability bounded by $e^{-\Omega(n)}$ when running on a probabilistic channel with error probability $\varepsilon < \varepsilon_0$.*

Proof Let X be a random variable denoting the number of inverted bits during a run of $\mathcal{P}$ on a probabilistic channel. Because transmission events are statistically independent therefore X has binomial distribution with probability ε of the success in a single event.

Running on a probabilistic channel, $\mathcal{P}$ fails with probability $\Pr(X \geq \varepsilon_0 n)$. From Tchebyshev exponential inequality we have that for any $\lambda \geq 0$

$$\Pr(X \geq \varepsilon_0 n) \leq \frac{\mathbb{E} e^{\lambda X}}{e^{\lambda \varepsilon_0 n}} = \left(\frac{\varepsilon e^\lambda + 1 - \varepsilon}{e^{\lambda \varepsilon_0}} \right)^n.$$

It is sufficient to show that $f(\lambda) = e^{\lambda \varepsilon_0} - \varepsilon e^\lambda - 1 + \varepsilon > 0$ for some $\lambda \geq 0$. We have $f(0) = 0$ and $f'(0) = \varepsilon_0 - \varepsilon > 0$. Hence $f(\lambda) > 0$ for some $\lambda > 0$. $\square$

Our construction is based on a generalization of Ulam's game [8]. We show the equivalence between a winning strategy in this game and a robust protocol. Ulam's game is widely considered in connection with one-direction data transmission over noisy channel and error correcting codes. However, its application requires the presence of noiseless feedback [1, 3], which is not realistic. We overcome the problem of noiseless feedback using a tree code introduced by Schulman [5].

We hope that the ideas presented in this paper can bring the results of [4, 5] closer to the edge of practical applicability. Our approach seems to be more practical because we use much shorter alphabet and we do not need back steps in protocol (like in [4, 5]), which make it much simpler.

2 Tree Code

Let us remind definition of Schulman's tree code from [5].

Definition 1 *A d -ary tree code over alphabet S , of distance parameter α and depth n , is a d -ary tree of depth n in which every arc of the tree is labeled with a character from the alphabet S subject to the following condition. Let u and v be any two nodes at some common depth h in the tree. Let $h - l$ be*

the depth of their least common ancestor. Let $a_1a_2 \dots a_h$ and $b_1b_2 \dots b_h$ be the concatenation of the letters on the arcs leading from the root of the tree to u and v , respectively. Then $H(a_{h-l+1}a_{h-l+2} \dots a_h, b_{h-l+1}b_{h-l+2} \dots b_h) \geq \alpha l$, where the Hamming distance H counts the number of positions i in which $a_i \neq b_i$.

We focus on the binary case $d = 2$ with distance parameter $\alpha = \frac{1}{2}$. Schulman [5] proves that an alphabet of size 95 suffices to construct such a code. The following theorem shows that only 16 letters are sufficient and achieved Hamming distance is a little better than $\frac{1}{2}$, as shown on Figure 1. Moreover our proof contains a randomized construction which in contrary to the proof from [5] almost surely gives a good code. A code over the alphabet $S_r = \{0, 1, 2, \dots, 2^r - 1\}$ is called an r -bit code. We can interpret S_r as the set of all possible r -bit vectors.

Theorem 1 *For every $n \geq 1$ and every $r \geq 4$ there exists an r -bit binary tree code of depth n satisfying*

$$H(a_{h-l+1}a_{h-l+2} \dots a_h, b_{h-l+1}b_{h-l+2} \dots b_h) \geq \begin{cases} l & \text{if } l \leq r, \\ r & \text{if } r < l \leq 2r, \\ l/2 & \text{if } l > 2r. \end{cases}$$

Figure 1: The Hamming distance lower bound for the r -bit binary tree code.

Proof Let t_0, t_1, t_{n-1} be a sequence of letters from S_r such that for $i < r$ they are linearly independent bit-vectors, e.g. $t_i = 2^{r-i} - 1$, and the remaining elements are chosen randomly with uniform distribution. We label arcs of the tree with alphabet $S_1 = \{0, 1\}$ so that arcs outgoing from each node to its sons have different labels. If $a'_1a'_2 \dots a'_h$ is the concatenation of the labels from the root to a node u over alphabet S_1 then as the label over alphabet S_r for the arc leading to the node u from its parent we take

$$a_h = \bigoplus_{i=1}^h a'_i t_{h-i},$$

where $\oplus$ denotes bitwise addition modulo two (exclusive or).

Let u and v be two different nodes at the same depth and w their least common ancestor. Let $a_1a_2 \dots a_l$ and $b_1b_2 \dots b_l$ be the concatenations of the letters over alphabet S_r on the arcs leading from w to u and v respectively. The Hamming distance between labels leading from the root to u and v is the number of nonzero elements in the sequence $c_1, c_2, \dots, c_l$, where $c_i = a_i \oplus b_i$. If $a'_1a'_2 \dots a'_l$ and $b'_1b'_2 \dots b'_l$ are the concatenations of the letters over alphabet S_1

on the arcs leading from w to u and v respectively and $c'_i = a'_i \oplus b'_i$ then we have

$$\begin{array}{rcl} c'_1 t_0 & & = c_1 \\ c'_2 t_0 \oplus c'_1 t_1 & & = c_2 \\ \vdots & & \vdots \\ c'_l t_0 \oplus c'_{l-1} t_1 \oplus \dots \oplus c'_1 t_{l-1} & = & c_l \end{array} \quad (1)$$

Observe that $c'_1 = 1$.

We can choose $2^{r(n-r)}$ different sequences $t_r, t_{r+1}, \dots, t_{n-1}$. We denote by $F(n)$ the number of those among them which violate the code condition (Hamming distance). Let $f(n, l)$ be the number of sequences which violate the code condition first time at distance l from the least common ancestor. Obviously we have

$$F(n) = \sum_{l=1}^n f(n, l).$$

Because $t_0, t_1, \dots, t_{r-1}$ are linearly independent bit-vectors and $c'_1 = 1$ then $c_i \neq 0$ for $i \leq r$. Hence $f(n, l) = 0$ for $l \leq 2r$. Therefore thesis holds when $n \leq 2r$ or $l \leq 2r$. Subsequently we assume that $n > 2r$ and $l > 2r$.

If l is even and the code condition is violated for some nodes at distance l then the number of zeros in the sequence $c_1, c_2, \dots, c_l$ is at least $l/2 + 1$. Hence the number of zeros in the sequence $c_1, c_2, \dots, c_{l-1}$ is at least $l/2$ and the code condition is violated already at distance $l - 1$. Therefore $f(n, l) = 0$ when l is even. Putting $l = 2m + 2r + 1$ we get

$$F(n) = \sum_{m=0}^{\lceil n/2 \rceil - r - 1} f(n, 2m + 2r + 1).$$

Now we count the number of bad sequences $c_{r+1}, c_{r+2}, \dots, c_l$ which can cause code violation first time at distance l . We use a notion of walks on the xy -plane, see Figure 2. We assign a walk to each sequence $c_1, c_2, c_3, \dots$. The value on the x -axis is distance l from the least common ancestor. The value on the y -axis is difference between doubled Hamming distance and l . We start at the point $(0, 0)$. Then we go by the vector $(1, 1)$ when succeeding c_i is nonzero and by the vector $(1, -1)$ otherwise. The walk corresponds to a bad sequence if it reaches the point $(l - 1, 0)$ never previously touching the line $y = -1$ and then it goes to the point $(l, -1)$. Because $c_i \neq 0$ for $i \leq r$ then after the first r moves we are at the point (r, r) . So the number of bad walks is the number of walks from (r, r) to $(l - 1, 0)$ such that they never touch the line $y = -1$. From the reflexion law this is the number of walks from (r, r) to $(l - 1, 0)$ minus the number of walks from $(r, -r - 2)$ to $(l - 1, 0)$. The number of walks from (x_1, y_1) to (x_2, y_2) is

$$\binom{x_2 - x_1}{(x_2 - x_1 + y_2 - y_1)/2}$$

if $x_2 - x_1 + y_2 - y_1$ is even and 0 otherwise. Consequently there are

$$\begin{aligned} & \binom{2m+r}{m} - \binom{2m+r}{m+r+1} = \binom{2m+r}{m} - \binom{2m+r}{m-1} = \\ & = \binom{2m+r}{m} - \frac{m}{m+r+1} \binom{2m+r}{m} = \frac{r+1}{m+r+1} \binom{2m+r}{m} \end{aligned}$$

bad walks. In each such walk, after the first r moves up, we go m times up and $m + r + 1$ times down. The moves up can be chosen on $(2^r - 1)^m$ ways because we have $2^r - 1$ nonzero choices for each c_i . The move down requires choosing 0 as c_i . Hence we have

$$B(m, r) = \frac{r + 1}{m + r + 1} \binom{2m + r}{m} (2^r - 1)^m$$

bad sequences $c_{r+1}, c_{r+2}, \dots, c_l$.

Figure 2: A walk on the xy -plane.

For every $r \geq 1$ there exists $\varepsilon > 0$ such that for any $m \geq 0$ holds

$$\frac{r + 1}{m + r + 1} \leq \frac{r}{2m + r} 2^{1+\varepsilon}.$$

It is sufficient to put $2^\varepsilon = \frac{r+1}{r}$. Therefore we have

$$B(m, r) \leq \frac{r}{2m + r} \binom{2m + r}{m} 2^{rm+1+\varepsilon}.$$

From equations (1) we conclude that for every bad choice of $c_{r+1}, c_{r+2}, \dots, c_l$ and for every choice of $c'_1, c'_2, \dots, c'_l$ there is at most one bad sequence of letters $t_r, t_{r+1}, \dots, t_{l-1}$ which violates the code condition first time at distance l . We have 2^{l-1} choices of $c'_1, c'_2, \dots, c'_l$ because $c'_1 = 1$. There are $2^{r(n-l)}$ sequences of $t_l, t_{l+1}, \dots, t_{n-1}$ to choose from. Therefore

$$\begin{aligned} f(n, 2m + 2r + 1) &\leq 2^{l-1+r(n-l)} B(m, r) = 2^{r(n-r)-r^2+r+2(1-r)m} B(m, r) \leq \\ &\leq \frac{r}{2m + r} \binom{2m + r}{m} 2^{r(n-r)-r^2+r+1+\varepsilon+(2-r)m} \end{aligned}$$

and

$$F(n) \leq 2^{r(n-r)-r^2+r+1+\varepsilon} \sum_{m=0}^{\lceil n/2 \rceil - r - 1} \frac{r}{2m + r} \binom{2m + r}{m} 2^{(2-r)m}.$$

From [2, formulas (5.68), (5.70)] we have that

$$\sum_{m=0}^{\infty} \frac{r}{2m+r} \binom{2m+r}{m} z^m = \left(\frac{1 - \sqrt{1-4z}}{2z} \right)^r.$$

We put $z = 2^{2-r}$. For $r \geq 4$ we have that $0 < z \leq \frac{1}{4}$, $1 - \sqrt{1-4z} \leq 2z(1+4z)$ and $(1+4z)^r = (1+2^{4-r})^r \leq 16$.

Replacing the finite sum with an infinite one we get

$$F(n) \leq 2^{r(n-r)-r^2+r+5+\varepsilon}.$$

Finally probability p , that randomly chosen sequence $t_r, t_{r+1}, \dots, t_{n-1}$ violates the code condition, does not exceed $2^{-r(n-r)} F(n)$. Hence

$$p \leq 2^{-r^2+r+5+\varepsilon} = \frac{r+1}{r} 2^{-r^2+r+5},$$

which for $r \geq 4$ is less than 0.01. $\square$

The above proof implies that in practice we can construct a good tree code with probability as close to 1 as we need. There are two possibilities. Either we choose appropriate r (already for $r = 8$ we have $p \leq 9 \cdot 2^{-54} < 5 \cdot 10^{-16}$) or we use computer to find the first q letters $t_0, t_1, \dots, t_{q-1}$ which maximize the Hamming distance. Then probability p decreases exponentially with q .

In next sections we use the 4-bit binary tree code. We use the following property of such code. Assume we are successively receiving letters $a_1 a_2 a_3 \dots$ describing a path from the root of the tree, and after each letter we are trying to identify a node to which this path leads. Then, if the total number of erroneously received letters is at most r , the Hamming distance property of the tree code causes that we badly identify the node at most $4r$ times.

It should be mentioned that the factor 4 is rough. In fact the code described in above proof can have better property.

3 Generalized Ulam's Game

Let us remind the definition of Ulam's game. There are two players Carole and Paul. The names come from Spencer [6]. Carole thinks of a number x between 1 and n . Paul asks at most q questions of the form "does $x \in F$?", where $F \subset \{1, 2, \dots, n\}$. Carole answers "yes" or "no" and she is permitted to lie at most l times. Paul wins if at the end of the game he knows x .

We propose a generalization of Ulam's game. Let $f: X_1 \times X_2 \times \dots \times X_k \rightarrow Y$ be a given function. Carole thinks of a tuple $(x_1, x_2, \dots, x_k) \in X_1 \times X_2 \times \dots \times X_k$. Paul asks at most q questions. In each question he chooses $i \in \{1, 2, \dots, k\}$ and he asks "does $x_i \in F_i$?", where $F_i \subset X_i$. Like in the original game Carole answers "yes" or "no" and she is permitted to lie at most l times. Paul wins if at the end of the game there is a unique possible value of the function f .

We allow Carole to play an adversary strategy. Carole does not actually pick a tuple but answers all questions so that there is always at least one tuple that satisfies all answers, except for at most l of them. We denote the generalized game by $\mathcal{G}(f, q, l)$. This game is determined. For given f, q, l either Paul or Carole has a winning strategy.

A winning strategy for Paul is represented by a tree.

Definition 2 *The strategy tree is a labeled binary tree. Each internal node is labeled with an index i and a set F_i . Arcs leading from each internal node to its sons are labeled with 0 or 1. Leafs are labeled with values of the function f .*

The interpretation is as follows. Paul starts at the root. In each internal node he asks the question “does $x_i \in F_i$?” found in the label of that node. If the answer is “yes” then he goes along the arc with label 1 and if the answer is “no” then he goes along the arc with label 0. If he reaches a leaf then he reads the value of f . The depth of the strategy tree is the pessimistic number of questions which have to be asked to win.

As we see in section 3.1 we can construct a winning strategy for Paul in the game $\mathcal{G}\langle f, n_0, 0 \rangle$. However usually it should be possible to construct a winning strategy in the game $\mathcal{G}\langle f, \lceil n_0/(k-1) \rceil, 0 \rangle$ because intuitively answering one question conforms to sending $k-1$ bits.

For standard Ulam’s game, if Carole is required to make sure that the fraction of lies is less than $1/3$ of her answers then Paul has a winning strategy with $\Theta(q)$ questions, where $q = \lceil \log_2 n \rceil$ is the number of questions which allows Paul to win in the game without lies [7]. We expect that for the generalized game a similar result holds.

Conjecture 1 *There exists a constant $\varepsilon_g > 0$ such that for every function f for which Paul has a winning strategy in the game $\mathcal{G}\langle f, n, 0 \rangle$, if the number of lies l is less than the fraction ε_g of all questions q ($l < \varepsilon_g q$), then Paul has a winning strategy in the game $\mathcal{G}\langle f, q, l \rangle$. Moreover $q \leq C_g n$, where C_g is a constant which depends only on l/q .*

Theorem 4 from [5] and considerations in section 3.1 imply that above conjecture holds for two-argument functions and with $\varepsilon_g = 1/240$. However we cannot construct a strategy because of a non-constructive proof in [5]. To make a practical benefit from above conjecture a constructive proof is needed.

Our main result can be stated not so formally as the following theorem.

Theorem 2 *There exists a lie-proof winning strategy for Paul in generalized Ulam’s game with the function f if and only if there exists an error-proof protocol for k processors computing the function f .*

Next subsections contain the appropriate constructions which explain the details.

3.1 Converting Protocol into Winning Strategy

Assume we have a protocol for k processors computing function $f: X_1 \times X_2 \times \dots \times X_k \rightarrow Y$. If some transmissions occur at the same time then we order them first by the number of the sender and next by the number of the receiver. So we have a protocol in which at every time-step exactly one processor P_i sends one bit to the another processor P_j . This bit depends on the input $x_i \in X_i$ and on bits which were seen by P_i before.

Paul simulates the run of the protocol. Assume that he knows all bits received by all processors up to the present. So Paul knows the processor P_i which should send a bit at present step. Hence he can compute the subset F_i of the set X_i such that $x_i \in F_i$ if and only if P_i sends 1 at the present step. Paul

asks “does $x_i \in F_i$?” . Answer “yes” means that processor P_j receives 1 and answer “no” means that processor P_j receives 0. If Carole tells the truth then this corresponds to a proper transmission of the bit. If Carole lies then this corresponds to the inversion of the bit during transmission. Hence Paul knows bit received at present step. By induction on the step number Paul knows all bits received by all processors in the run of the protocol. This sequence of bits is called the *protocol trace*.

Because at the end of the protocol all processors know the same value of the function f then the protocol trace determines this value and Paul knows it, as well. Therefore if the protocol exchanges q bits and is proof against l errors then we have winning strategy for Paul in the game $\mathcal{G} \langle f, q, l \rangle$.

3.2 Converting Winning Strategy into Protocol

Assume we have a winning strategy for Paul in the game $\mathcal{G} \langle f, q, l \rangle$. We call it shortly a strategy. The state of the game is the location in the strategy tree. We identify the state with the tree node. If v is a state then by va we denote the son of v to which leads the arc labeled with a , where $a \in \{0, 1\}$. Let for a node v the symbols $i(v)$ and $F(v)$ stand for the index and set used by Paul in his question, respectively. I.e., in node v Paul asks “does $x_{i(v)} \in F(v)$?”. Let $[\varphi]$ be 1 if the condition φ is true and 0 otherwise.

The strategy corresponds to the following protocol. All processors maintain the same state. The initial state is the root. In the state v processor $P_{i(v)}$ broadcasts bit $a = [x_{i(v)} \in F(v)]$ to all other processors. The transmitted bit can be inverted, but all the processors receive the same value $\hat{a}$. Moreover we have to assume that there is a feedback to the sender and it knows what bit has been received by others. Next all the processors change their state according to the received bit, to the new state $v\hat{a}$. If processors reach a leaf then the protocol ends. It is clear that if the number of faulty broadcasts does not exceed the number of lies for which the strategy was developed then all the processors properly compute the value of the function.

The above scenario is not realistic and does not correspond precisely to our communication model. We show how to convert this protocol into another protocol in which we need neither broadcast nor error-free feedback.

The first problem we have to overcome is the possibility of protocol deadlock. This happens if $i(v0) \neq i(v1)$ and processors $P_{i(v0)}$ and $P_{i(v1)}$ receive 1 and 0 respectively. In this situation all processors will wait for a message forever. We consider *semi-static strategy* in which all indices at same depth in the strategy tree are the same. Every strategy of depth q can be easily converted into a semi-static one, of depth $q' \leq kq$. Moreover we can assume that all leafs in the new strategy tree are at the same depth. In other cases we can easily extend the strategy tree so that it has this property.

We label the strategy tree with a tree code using the alphabet S_4 . Let $S(v)$ denote the letter on the arc leading to v from its parent.

Now we have the following protocol. Processor P_j maintains the state v_j . Processor P_1 maintains its own state. Other processors maintain expected state of processor P_1 . At beginning all states are the root.

Protocol consists of rounds. In each round all states are at the same depth in the strategy tree. Because we consider semi-static strategy then in each round all processors know the same value $i = i(v_j)$. In each round processor P_i sends

$a = [x_i \in F(v_i)]$ to P_1 . Say that P_1 receives $\hat{a}$. If $i = 1$ then P_1 does not need to send anything to itself and we assume that $\hat{a} = a$. Next processor P_1 changes its state to $v_1\hat{a}$ and sends $s = S(v_1\hat{a})$ to all other processors. Transmission can be corrupted and processors can receive different bits. Say that for $j \neq 1$ processor P_j receives $\hat{s}_j$. Next P_j updates the state v_j using the tree code property. Protocol ends when processors reach a leaf.

Let q_1 and q_2 be the number of messages received and sent by processor P_1 , respectively. Let r_1 and r_2 be the number of erroneous messages received and sent by processor P_1 , respectively. The protocol works fine if $r_1 + 4r_2 \leq l$. Hence it is proof against at least $l/4$ bit-errors. The protocol exchanges $q_1 + 4q_2$ bits. We have $q_1 \leq q' \leq kq$ and $q_2 = (k-1)q' \leq k(k-1)q$. Hence the protocol exchanges at most $k(4k-3)q$ bits. Therefore it is proof against at least the fraction

$$\frac{l}{4k(4k-3)q} \quad (2)$$

of badly transmitted bits.

We can increase robustness of the above protocol by running it parallel on all processors. Now each processor P_j maintains k states $v_{j1}, v_{j2}, \dots, v_{jk}$. The state v_{jj} is own state of the processor P_j . For $m \neq j$ the state v_{jm} is the state of the processor P_m predicated by the processor P_j .

Protocol consists of rounds. In each round all states are at the same depth in the strategy tree. Because we consider a semi-static strategy then in each round all processors knows the same value $i = i(v_{jm})$. In each round for each $j \neq i$ the processor P_i sends $a_j = [x_i \in F(v_{ij})]$ to the processor P_j . Say that P_j receives $\hat{a}_j$. If $j = i$ then P_i does not need to send anything to itself and we assume that $\hat{a}_i = a_i$. Next for each j processor P_j changes state to $v_{jj}\hat{a}_j$ and sends $s_j = S(v_{jj}\hat{a}_j)$ to all other processors. Say that for $j \neq m$ processor P_j decodes letter from processor P_m as $\hat{s}_{jm}$. Then P_j updates the state v_{jm} using the tree code property. Protocol ends when processors reach a leaf. Each processor has k values of the function. It is sufficient that at least $\lfloor k/2 \rfloor + 1$ of them are correct.

4 Conclusions

Presented calculations are very rough because our principal aim is to show that we can construct a robust protocol from a strategy in the game and we want to show this as simple as possible. In fact a single bit error by transmitting a letter from the 4-bit tree code may not cause an error by decoding this letter. Probably in practice a protocol constructed from a good strategy have better properties than expressed by (2).

Further work should concentrate on proving Conjecture 1. Constructive proof which already gives semi-static strategy is desired. Such a proof would give another proof of Schulman's Coding Theorems [5]. We hope that this approach should give less communication overhead.

Another direction of research is searching for an efficient deterministic construction of a tree code and development of an efficient algorithm for tree code decoding. A "efficient" means working in time linear in the depth of the node in the tree. Some advice how linear time decoding could be done is given in [5].
